Non-Equilibrium Conditions and Diffusion Creep in Metallo-TITLE: Ceramic Bodies (Neravnovesnyye sostoyaniya i diffuzionnaya

polzuchest' u metallokeramicheskikh tel)

PERIODICAL: Fizika metallov i metallovedeniye, Vol 7, Nr 5, pp 766-776 (USSR) 1959

ABSTRACT: In order to appreach the conditions of diffusion creep experiments were carried out at relatively high temperatures Creep investigations under and low applied stresses. conditions of strain were carried out on metallo-ceramic specimens made by pressing powders of copper (electrolytic), nickel (carbonyl), iron, and mixtures of these metals. The grain size of Cu and Ni powder was 10-15 µ and that of iron powder 30-40 ... The specimens were made in the shape of rods of 3 x 3 mm cross-section and a working length of 90 mm, with special heads of larger cross-section. The initial perosity of all specimens was 30-32%. The creep experiments were carried out at temperatures of up to Card 1/6 1250°C in a vacuum apparatus shown in Fig.1. The apparatus

and a committee of the committee of the

SOV/126----7-5-21/25 Non-Equilibrium Conditions and Diffusion Creep in Metalle-Ceramic

> was evacuated by means of the diffusion oil pump MM-40. Loading of the specimens to be pulled was carried out with the help of an electromagnet. The grips in which the specimen heads were held were made of stainless steel and had a cross section one and a half times greater than that of the specimens, hence they remained practically undeformed in the experiments. The elongation of the specimens was determined according to the angle through which an indicating In Fig.2 creep curves (dependence of mirror had turned. the elongation $\Delta l/l$ on time t) for various specimens at Fig. 3a shows the concentration depen-1000°C are shown. dence of the complete elongation $\Delta l/l$ for 4 hours. shows the concentration dependence of the initial creep rate v for Cu-Ni specimens after preliminary annealing. The state of the s

SOV/126- 7-5-21/27

Non-Equilibrium Conditions and Diffusion Creep in Metalla-Geramia Bodies

conclusions

- 1. Metalla-Geramia specimens compressed from powders of pure metals and mixtures of metallic powders exhibit diffusion creep at high temperatures. At first a stage of unestablished creep is observed, in which deformation decreases with time. This is followed by a stage in which creep is established at a constant deformation rate.
- 2. Preliminary annealing of metalls—ceramic specimens decreases the initial rate and extent of the full creep deformation. After a sufficiently lengthy preliminary annealing treatment the first creep stage disappears completely.
- 3. Gold working (compression at room temperature) increases the initial rate and extent of the full deformation in diffusion creep at high temperatures. After cold working the first creep stage, which had been removed by preliminary annealing, is re-established.

4. Metalla-ceramic specimens made from mixtures of powders of metals diffusing into each other exhibit a much greater initial creep rate which corresponds to the first stage. After lengthy annealing the initial creep rate and the full deformation in creep decrease sharply.

Card 4/6

The state of the s

SOV/126- - 7-5-21/25 Non-Equilibrium Conditions and Diffusion Creep in Metallo-Ceramic Bodies

- 5. The creep deformation of a porous metallo-ceramic specimen which is brought about by straining at high temperatures noticeably decreases the sintering rate of the specimen.
- 6. Specimens with different initial porosities have different initial creep rates. After annealing, the creep rates of the specimens become identical.
- 7. The initial creep rate and the rate at which creep is established subsequently for metallo-ceramic specimens depend on the applied stress and are somewhat greater than that according to linear law. This may be due to departure from equilibrium conditions.
- 8. The activation energy of the creep process in one-component metallo-ceramic bodies is less than the equilibrium activation energy of volume self-diffusion. Only in iron powder specimens having undergone preliminary annealing the activation energy of creep (particularly the Y-phase) approaches the equilibrium value of the activation energy of self-diffusion. For specimens made of mixtures of various

Card 5/6

Control of the second state of the second second

SOV/126---7-5-21/25

Non-Equilibrium Conditions and Diffusion Creep in Metallo-Ceramic Bodies

metal powders, having undergone lengthy annealing treatment, the activation energy of creep depends on the concentration of the mixtures according to the linear law.

9. The mechanism in the creep of metallo-ceramic specimens can be explained only on the basis of a diffusion mechanism in which non-equilibrium conditions causing an increase in the value of the self-diffusion coefficient and a decrease in activation energy are taken into consideration.

Service Time Under Load as Dependent on the Applied Stress for Metalloceramic Iron Samples in the \propto and γ Phase

PERIODICAL:

Doklady Akademii nauk SSSR, 1959, Vol 129, Nr 2, pp 310-313 (USSR)

ABSTRACT:

Introducingly a report is made on various previous investigations dealing with this subject. According to S. N. Zhurkov and coworkers (Refs 1, 2) the following dependence of the service time T on the load p and on the temperature T is experimentally observed:

<u>E- }-</u>

 $\mathcal{T} = \mathcal{T}_0 e^{kT}$. In this case k denotes Boltzmann's constant,

To and y constants of the material, E - activation energy of the destruction processes the numerical value of which is the same for some metals with high heat of sublimation. The experiments described in the present paper were made with metalloceramic samples (length 30 mm, operating length 20 mm, cross section 3×3 mm²) which were pressed from iron dust with the grain size $< 50 \,\mu$ (average $\sim 30 \,\mu$). Samples of different porosity were

Card 1/4

66735

Service Time Under Load as Dependent on the Applied SOV/20-129-2-20/66 Stress for Metalloceramic Iron Samples in the \propto and γ Phase

produced. The annealing of the samples is described in brief. The authors determined the service time under load for several samples of different porosity and by extrapolation to the value zero the value corresponding to a massive sample was determined. The change in service time due to porosity was only some per cents. The service time under load was determined at the temperatures of 600; 800; 900; 1000; and 1100° in a vacuum apparatus at pressures of $\sim 10^{-4}$ to 10^{-5} torr and in an interval of loads in which the service time varied by 3 to 4 orders of magnitude. The results of these experiments are illustrated by two diagrams. The calculated and the experimental curves are in agreement at the following values of the constants in the formula given by B. Ya. Pines (Ref 4):

Card 2/4

Service Time Under Load as Dependent on the Applied SOV/20-129-2-20/66 Stress for Metalloceramic Iron Samples in the \propto and γ Phase

at 1000° and 1100°: C = 5, $\alpha = 450 \text{ mm}^2$.degree/kg, $U_0^{\alpha} = 68$ to 70 kcal/g mol. In the above formula C denotes a numerical factor of the order one, δ - the linear size of the atoms, n_0 - the number of the vacancies, the combination of which corresponds to an initial "germination crack", D - the coefficient of autodiffusion. Moreover it holds that

 $\propto = \int_0^3 \sqrt{n_o/k}$. The values found for the activation energy of the destruction processes are in good agreement with the known values of the activation energy iron autodiffusion in the \propto and f-phase. The concepts of diffusion are in complete agreement with the experiments described here. The problem of the service time of the alloys under stress has still to be subjected to an exact

Card 3/4

66735

Service Time Under Load as Dependent on the Applied SOV/20-129-2-20/66 Stress for Metalloceramic Iron Samples in the \propto and γ Phase

theoretical and experimental investigation. The second diagram shows the dependence of service time on temperature for different constant values of p. Above the point of the α - γ -phase transformation the service time increases jump-like. There are 2 figures and 6 Soviet references.

AUTHORS: TITLE:

The Problem of the Role of Closed Pores in Sintering in

Powder Metallurgy

PERIODICAL: Izvestiya vysshikh uchebnykh zavedeniy, Fizika,

1960, Nr 1, pp 23 - 28 (USSR)

ABSTRACT:

The variation of final porosity of $\eta_{\mathbf{k}}$ of a sintered

specimen with initial compaction pressure P was studied for various sintering schedules. Figure 1 taken from Ref 3 shows the relationship between the initial porosity η_H

(largely determined by P) for ∠ 50 μ Cu powder after heating to 1 000 °C and Curve 1 - immediately cooling,

Curves 2, 3, 4, sintering for 15, 60 and 240 min. Minimum $\eta_{\mathbf{k}}$ is found near 27% $\eta_{\mathbf{H}}$ and for the lowest

lying curve, 4, is about 10%. The non-monotonic relationship is due to gas pressure in the pores. Decrease does increase the area of intergranular contact

thus increasing sintering rate, but also increases the number of closed pores which tends to give reduced sintering

Card1/4

69430 S/139/60/000/01/004/041

The Problem of the Role of Closed Pores in Sintering in Powder Metallurgy

rate. Ref 3 also gave data on rates of shrinkage of unpressed powders of Cu both pure and with additions of other metals (low-melting). These are plotted in Figure 2 whence it can be seen that very large shrinkages were obtained, particularly with mixtures (e.g. Cu + 3% Pb, ~70% after 5 hours at 1 000°). Pressed mixtures (4.6 tons/cm²), however, showed an expansion (Curves 7-9) though pure Cu (Curve 6) did not. The effect of vacuum pressing at 10^{-1} - 10^{-2} mm Hg was now tried, a photograph of the special press being shown in Figure 3. Figure 4 shows $\eta_k - \eta_H$ plots for Cu so prepared after various holding times at 1 000°; η_k decreases monotonically with η_H and can be as low as 5% for 8% η_H ; sintering in H_2 or in vacuum gave almost identical results. If, however, oxidized Cu powder was used a minimum was again

Card2/4

V

The Problem of the Role of Closed Pores in Sintering in Powder Metallurgy

obtained (Figure 5); this was ascribed to release of gas on decomposition of the oxide. Some gas is probably still present, perhaps as oxide, in vacuum-pressed specimens, since unpressed specimens have $\eta_k = 2\%$ after 8 hours at 1 000 and 1% after 12 hours. Further work was concerned with Ni-Alvalloys. Trapped gas can cause marked bloating, as indicated in Figure 6, which suggests that this can largely be avoided by heating for several hours at 620 (below the melting point of Al) prior to sintering at 1 250 C (specimen 5, 30% Al), since

marked bloating, as indicated in Figure 0, which suggests that this can largely be avoided by heating for several hours at 620° (below the melting point of Al) prior to sintering at 1 250°C (specimen 5, 30% Al), since specimens 2-4 (10, 20 and 30% Al) heated directly to 1 250° bloated badly. Pure Ni (Specimen 1) showed no such effects. Bloating is ascribed to formation of liquid Al which rapidly seals any pores and prevents the escape of gas. Some reaction between Ni and Al occurs at 620° as indicated in Figure 4, which shows plots of shrinkage (for 1, 3 and 8 hours heating) as a function of composition. The relatively large expansion for intermediate compositions (maximum at ~ 50% alloy) is not due to bloating but to alloy

Card3/4

69430

5/139/60/000/01/004/041

The Problem of the Role of Closed Pores in Sintering in Powder Metallurgy

formation. Under the microscope it is found that Al particles tend to disappear while the (initially) Ni particles expand (Figure 8 for 30% Al mixture, 8 hours at 620 °C, then heated to 1 250 °C and immediately cooled. x 400). Finally, Figure 9 shows shrinkage as a function of composition for 1, 3 and 5 hours at 1 250 following heating for 8 hours at 620 °C. There is a slight expansion for mixtures ~15 - 45% Al. It is emphasized that, in sintering a mixture of materials, it is important to outgas at temperatures below the melting point of any constituent. There are 9 figures and 3 Soviet references.

Diffusion Creep and Non-Equilibrium State in Metal Ceramics and Cast Metals

They can be fully eliminated by sufficiently extended high-temperature annealing. Furthermore, investigations were carried out into creep after hard facing of metal ceramics pressed from iron powder. Results of experiments are given in Table 2. It was established that hard facing speededup diffusion creep at high temperatures (e.g. in iron at 900°C) mainly at the unsettled stage. At lower temperatures (700°C for iron) hard facing caused a decrease in the creep pate. This proves that creep at such temperatures has not a purely diffusion but probably a dislocation nature. Results obtained from experiments with Co-Ni, Ni-Fe and Ni-W powders [Ref 6] were analogous to those obtained with other systems including the Cr + Mo systems. Pure component and 50% Cr + Mo powder mixtures were tested at 1,300°C in a vacuum under a load of 75 g/mm². The samples were preliminary annealed in a vacuum at 1,300°C and 1,500°C for up to 14 hours. Besides deformation creep, shrinkage in sintering during preliminary annealing was studied. Results of experiments are given in Figure 4. It was established that diffusion creep was always accelerated (mainly at the unsettled stage) in samples having excessive vacancies, arising as a result of non-uniform partial heterodiffusion. In metal ceramic samples of Cr and Mo powder mixtures, the creep Card 2/3

S/148/60/000/002/005/008

Diffusion Creep and Non-Equilibrium State in Metal Ceramics and Cast Metals

acceleration was correspondingly low at $1,300^{\circ}\mathrm{C}$, when heterodiffusion occurred. Annealing at $1,500^{\circ}\mathrm{C}$ during 50 minutes delayed the creep of pure component samples; on the other hand, the creep of powder mixtures was accelerated. After extended annealing (8 hours) creep of powder mixtures was slowed down due to the gradual elimination of excessive vacancies.

Calculated and Experimental Values of the Durability of Loaded Metals and Alloys

81615 s/181/60/002/06/03/050 B122/B063

Previous papers by the authors had shown that the activation energy To of the process leading to a rupture of the sample, and the values of the activation of self-diffusion are practically equal (Refs. 2,4), but that

constants, involves some difficulties in the determination of U_0 (Ref. 3). the use of the empirical formula (2) T = Ae Experiments on Sn, Pb, and Cu as well as a comparison of data known from publications concerning the durability of the metals Al, Pt, and Ag under load showed that the durability T as dependent on p and T is very well reproducible by formula (1) in experiments conducted at room temperature and higher temperatures. On a proper selection of coefficient C in formula (1), the activation energy of the tearing process for all metals within the error limits is in fairly good agreement with the activation energies of self-diffusion. When trying to determine the activation energy from formula (2), in which, since A = const., the pre-exponential factor is independent of P and T, only few empirical constants were obtained, and not Uo itself. Formula (2) cannot be used to calculate U. of allows. Figs. 1-7 show experimental and coloulated to calculate Uo of alloys. Figs. 1-7 show experimental and calculated

"Recovery" Under Load in Processes of Diffusion Cree

Ceramics

PERIODICAL:

Izvestiya vysshikh uchebnykh zavedeniy, Chernaya metallurgiya,

1960, Nr 5, pp 121 - 129

Diffusion creep in porous metal ceramics was studied by experiments made with specimens pressed from copper powder (electrolytic origin; grain size $\leq 50 \mu$), nickel powder (reduced from carbonyl; grain size 10 - 15 μ) and tungsten (grain size 5 - 10m). The experiments are illustrated by a number of graphs. It was established that metal, alloy and, particularly, metal ceramic specimens, subjected to diffusion creep at raised temperatures, rsysaled considerable retardation of other diffusion processes, such as sintering, recrystallization and heterodiffusion. This retardation was connected with the non-equilibrium state of the specimens and arose in connection with the gradual approach to the equilibrium. Diffusion coefficients decreased correspondingly. Thus, speeded-up "recovery" of equilibrium properties under

TITLE:

The Problem Concerning the Conditions of Reversibility of the Destruction Processes of Metals Under Load

PERIODICAL: Doklady Akademii nauk SSSR, 1960, Vol. 131, No. 6, pp. 1312 - 1315

Andrew Commission of the Commi

TEXT: The experiments described were made with powder-metallurgical samples which were pressed from electrolytic copper. The samples had an initial porosity of 17 - 18%, which was reduced to 3 - 4% by sintering at 1050°C (for 24 hours). The life of a series of 35 equal samples was determined after applying the same load in each case. From these values the average life was determined. The life of a further series of 35 samples under load was determined after intermediate annealing. Also in this case the average life was determined. In Fig. 1 the results of life determination at room temperature without intermediate annealing and of life in the case of intermediate annealing at 600°, 900°, and 1040°C are graphically represented. In Fig. 2 the analogous results of durability determination under stress at 600°C are shown. It is found that intermediate annealing of four hours at 1040°C produces the same results as intermediate annealing for ten

Card 1/2

80085

The Problem Concerning the Conditions of Reversibility 5/020/60/131/06/23/071 of the Destruction Processes of Metals Under Load B014/B007

hours at 900°C; for a complete healing of defects, annealing for 35 hours at 1040°C is necessary. Fig. 3 graphically represents the dependence of the quantity $\Delta \tau = \overline{\tau_1 + \tau_2} - \overline{\tau}$ on the time t (τ_1) and τ_2 are the life before and after inter-

mediate annealing, $ilde{ au}$ is the mean life without intermediate annealing). Herefrom, conclusions are drawn as to the diffusion-character of healing. By extrapolation of the straight lines obtained from the experimental data, the annealing time necessary for complete healing of the defects is determined as being 105 hours at 600°C, and as being 16 hours at 1040°C. The ratio between these two times is about 7.2 and corresponds to the ratio between the coefficients of the selfdiffusion of copper at these two temperatures. Thus, all arguments indicating the diffusion-character of the growth of cracks after stresses are strengthened. There are 3 figures and 5 references, 4 of which are Soviet.

The Mechanism of the Rupture Life of Metals Under Stress

PERIODICAL: Doklad

Doklady Akademii nauk SSSR, 1960, Vol. 134, No. 5,

with the measurement for the second s

pp. 1061 - 1064

TEXT: Attempts have been made in previous papers to explain the rupture life of metals under stress as a diffusion of microcracks rising to a critical size in metals with a subsequent avalanche-like growth of the cracks. Other authors have been able to prove that the activation energy of the rupture process practically coincides with the activation energy of self-diffusion, and have thus again confirmed this view. The article under consideration reports on tests made on metalloceramic Cu-specimens, which confirm the diffusion mechanism. The copper specimens all had a composition deviating from the state of equilibrium. Rupture life under stress at room temperature, at 600° , 900° , and 1040° C was investigated. To avoid plastic deformations, the specimens had a sharp notch in the middle of the gage length. Tests revealed that the

Card 1/2

The Mechanism of the Rupture Life of Metals Under Stress

\$/020/60/134/005/011/023 B019/B060

rupture life of specimens at room temperature is the same as in electrolytic copper. Differences, however, become considerable at higher temperatures. Preliminarily strain-hardened - cold-worked from 20 to 50% reduction - sintered specimens had a rupture life which was the shorter the higher the reduction. The shortest rupture life was recorded for electrolytic copper. These results are believed to confirm the theory of the diffusion mechanism of metal rupture under stress. There are 3 figures and 8 Soviet references.

measurements were carried out under stresses of 130-2500 g/mm² at 800, Concentration dependence of creep ... 900 and 1000°C. Results: In Fe-C alloys the creep rate is proportional to the self-diffusion coefficient at all temperatures and concentrations. The same tendency, was observed at Fe - Cu. In Fe - Cu alloys the concentration dependence of the creep rate is a non-linear function at all temperatures; it is always lower than would be implied by a linear law. This fact is attributed to a boundary effect of the different types of grains. The creep rate V is a power function of the stress p: V~p. For Fe-C n = 4.0, for Fe-Cu n = 4.3-4.5. As regards stresses which are not too small, this is in agreement with experimental data. In first approximation log V7 is independent of stress and temperature (t - longevity under stress) but depends on the structural state and concentration of the alloy. It differs greatly for cast and powder-metallurgical specimens of the same concentration and depends greatly on metallurgical specimens of the same concentration and depends greatly on the heat treatment. For Fe = Cu alloys, log Vt varies most strongly in the single-phased regions and weakly in the two-phased regions of the confidence of log Ve is not in the single-phased regions and weakly in the two-phased regions of log Ve is not in the confidence of log Ve is not in the equilibrium diagram. The approximate constancy of log Vt is not inconsistent with the relation $V \sim Dp^n$ and that obtained for τ by Pines

A CONTROL OF THE PROPERTY OF T

forms of the X-ray powder lines

PERIODICAL: Kristallografiya, v.7, no.1, 1962, 20-30

TEXT: An examination is made of the errors arising in the Fourier analysis of the form of lines in an X-ray powder photograph because of the inexact separation of the line from the background. It is shown that errors of this kind lead to a parallel displacement of the ordinates of the Fourier transform in the semi-logarithmic plot of $z=-\log A_n=z(n)$, where A_n is the n-th order Fourier coefficient. It is shown that the errors conditioned by the differences between the calculated Fourier coefficients, reckoned over an infinite interval, and the coefficients corresponding to a finite interval of subdivision for the case of the Cauchy curve, also produce a parallel displacement of the ordinates of the curve $z=-\log A=z(n)$. A calculated verification, carried out from synthetic curves of the Cauchy type, Card 1/2

the state of the same of the s

The determination of ...

of the Gaussian type and of mixed type, showed that the departure of the experimentally constructed curve of $z=-\log A_n=z(n)$ from the calculated one always leads to a parallel displacement of the ordinates of the curve. On this basis a general method of analysing an interference line appears to be the construction of the Fourier transform and the approximation by the function $z=z_0+Mn+Nn^2$ to the values found for $z=-\log A_n$. The coefficients M and N can be found from the experimental values of z for all integral values of n except n=0. There are 4 figures and 1 table.

On the problem of

conditions. The test temperature ranged from 800-1100 °C for Ni, from 600-1100 °C for Fe and from 20-350 °C for Al, the figures for the applied stress being up to 6 kg/mm for Al, the 5 kg/mm for Fe and up to 16 kg/mm for Al. All the three metals studied in the annealed condition had a time-to-rupture γ longer and a rate of steady creep v slower than the cold-worked specimens; this applied to tests carried out at elevated temperatures, cold-working and annealing having an opposite effect on γ and v at room temperature. In the case of Fe, the beneficial effect of high-temperature annealing on γ was observed in α -Fe only, no difference between cold-worked and annealed specimens having been observed in specimens tested in the γ -range, i.e. at temperatures higher than 910 °C. This finding supported the hypothesis that the effect of annealing was associated with "healing" of the crystal-lattice defects. Finally, the product τv of cold-worked specimens was found to be lower than that of annealed materials, this difference increasing with increasing degree of preliminary, cold plastic deformation. There are 4 figures.

TITLE: Speed of the diffusive creep in metals at submelting temperatures

SOURCE: Fizika metallov i metallovedeniye, vol. 15, no. 4, 1963, 584-591

TOPIC TAGS: creep in metal , creep in copper, velocity of creep

ABSTRACT: According to the existing postulates, the diffusive creep in the homogeneously stressed bodies is caused by the existence of atomic sources and voids inside and at the periphery of the body. The formulas expressing the speed of a steady diffusive creep derived by C. J. Herring, I. M. Lifshits, J. Harper, L. Shepard, and J. Dorn are compared; the theoretical and experimental data concerning the effect of the specimen substructure on the creep velocity are discussed. The experiment involved the study of the creep velocity variation (under tension) in 13 electrolytic copper samples. The samples, differing in grain sizes, were subjected to various treatments before experiment. The creep velocity measurements in all the samples were made at the same temperature (1040C) and load (p=25g/mm²). The experimental conditions corresponded to the diffusive

c 1/2

L 18052-63

ACCESSION NR: AP3000101

creep the velocity of which depends on the applied stress p. The creep velocity variation observed in these specimens was in the interval from 5.6 x 10⁻² 1/sec to 3×10^{-8} 1/sec. The authors conclude that the difference in the speed of a steady creep at the temperature 1040C may amount to more than 3 orders of magnitude and that this speed varies on the structural and substructural state of the specimen, determined by the kind of the preliminary treatment. However, neither of the assumed substructure types, which determine the distance between the atomic sources and voids, can explain the broad range of velocity variations. Possibly the effects obtained experimentally were caused by the superposition of various substructure types. Orig. art. has: 4 formulas, 1 table, and 6 figures.

TITIE: Formation of diffusion porosity in self diffusion	
matter tyordogo tela. v. 7, no. 3, 1965, 687-694	
TOPIC TAGS: diffusion porosity, self diffusion, vacancy motion, dislocation motion, pore formation, crystal lattice distortion ABSTRACT: To determine the conditions under which diffusion porosity appears via self diffusion, and the laws governing its development, several experiments were carried out in bodies made up of parts of the same material (copper) but of different structure (cast, highly annealed, deformed [cold hardened], and metal-ferent structure (cast, highly annealed, deformed [cold hardened], and metal-ceramic). The tests have shown that heating a composite body consisting of atoms of one kind but containing parts with different degrees of crystal-lattice distortion leads to the occurrence of diffusion porosity in that part of the body where the lattice distortions are smaller. The presence of porosity in parts of the body having larger distortion (larger dislocation density) does not hinder the body having larger distortion (larger dislocation density) does not hinder the development of diffusion porosity in the part closer to thermodynamic equilibrium

2

even when pores of smaller radius than in the distorted section are obtained in the section closer to the equilibrium. These pores no longer serve as sinks for vacancies. If closed pores filled with gas are present in the distorted part of the body, this part does not shrink upon heating, but grows (under the influence of the gas pressure), i.e., the pores become sinks for vacancies and the formation of diffusion porosity in the neighboring less distorted regions of the body greatly decreases, or may stop completely. "Student P. A. Flomina participated in the experimental part of the work." Orig. art. has: 6 figures, 3 formulas, and 1 table.

Absorption of Energy During Low Temperature Deformation of Nickel

PERIODICAL: Uch. zap. Khar'kovsk. Un-t, 1958, Vol 98, Tr. Fiz. otd. fiz.-matem. fak., Vol 7, pp 359 - 363

ABSTRACT: The authors investigated the effect of the deformation temperature

on the magnitude of latent Ni deformation energy within the temperature range of liquid N₂ and room temperature. The following perature range of liquid N₂ and room temperature. The following pulse method was used for measurements. Deformed and standard pulse method was used for measurements. Deformed and standard specimens were connected to a bridge circuit and current pulses of a short duration (0.01 - 0.02 sec) were passed through. The pulse intensity was sufficient to anneal the hard-faced specimen. During the annealing process, due to the liberation of latent deformation energy, the bridge balance changed; this served as a criterion to calculate the latent deformation energy. The error of measurement was about ~7%. The specimens consisted of wires

of measurement was about $\sim 7\%$. The specimens constrained by Card 1/2 of 0,25 mm diameter and ~ 50 mm length. They were deformed by

SOV/137-59-5-10790

Absorption of Energy During Low Temperature Deformation of Nickel

compression between two plane parallel plates. It was established that a decrease in the deformation temperature caused an increase of the latent deformation energy from 0.53 cal/g at room temperature to 2.2 cal/g at $77^{\circ}\mathrm{K}$. The energy consumed for deformation did not remain constant, but decreased from 17.5 to 5.38 cal/g, respectively. Consequently, during constant work the temperature dependence of the latent deformation energy will be still more pronounced. Results obtained confirm the assumption that relaxation processes occur with sufficient intensity even at room temperature. In the investigated range of temperatures the linear dependence between the increment $1/\rho$ and the magnitude of latent deformation energy for Ni was established.

TITLE: X-ray Study of Deformation of Metal Crystal Lattices,

Deformed at Low Temperatures

PERIODICAL: Fizika metallov i metallovedeniye, 1959, Vol 8, Nr 2,

pp 235 - 239 (USSR)

ABSTRACT: Deformation at 77 oK of commercially pure iron and

aluminium and spectrographically pure lead was studied. The specimens were initially free from distortion and were deformed by uni-axial compression at both room temperature and temperature of liquid nitrogen. The latter samples were investigated in a low-temperature X-ray chamber (Figure 1). The specimen was partly immersed and also sprayed by liquid nitrogen, giving a variation of less than $\pm 0.2^{\circ}$. An approximate method (B. Ya. Pines - Ref 8) was used to distinguish between the effects of "fine dispersion" and "micro-distortion".

Figure 3 shows that even at small deformations (2-5%) a fine dispersion is developed with coherent regions of

Cardl/3 approximately 10⁻⁵ cm. With greater deformation these

SOV/126-8-2-12/26 tal Lattices. Deformed at

X-ray Study of Deformation of Metal Crystal Lattices, Deformed at Low Temperatures

regions increase in size by 2-3 times. Figures 4 and 5 show the relation between micro-deformations and distance for aluminium and armco iron. Similar curves were obtained for lead. These show that the main effect of distortion of the crystal lattice is obtained at the very beginning of deformation. Deformation at low temperatures produces more micro-distortion than at room temperature. Curves of relative micro-deformation at low temperature are shown in Figure 6. These show it is This maximum inhomogeneous and passes through a maximum. increases with increasing deformation and decreasing temperature. Micro-stresses in the samples were calculated and an attempt was made to relate them to creep limit. It was shown that the micro-stresses are always less than the creep limit. Figure 7 shows that a linear relationship exists between the micro-deformation of the lattice and the creep limit. A similar relationship occurs with

Card 2/3

SOV/126-8-2-12/26

X-ray Study of Deformation of Metal Crystal Lattices, Deformed at Low Temperatures

hardness. From the obtained data, the mean values of the elastic energy of deformation were calculated. With 50% deformation at 77 K there are 0.02, 0.09 and 0.34 cal/mol for lead, aluminium and iron, respectively. These values are only small percentages of the total latent energies of deformation. There are 7 figures and 14 references, of which 10 are Soviet and 4 English.

ABSTRACT: It has been shown in previous papers (Refs 1, 2) that a lowering of deformation temperature leads to a considerable decrease in the size of coherent scattering regions and to an increase in micro-stresses. detailed study was intended of the nature of the dependence of these factors on the deformation temperature in a wide temperature range, particularly at Massive specimens of technically pure aluminium and spectroscopically pure lead were plastically deformed by uniaxial compression at 90, 195, 255 and 293 °K. Immediately after deformation, without 255 and 293 ok. Immediately after deformation, without intermediate annealing, the specimen was placed in a low-temperature chamber (see Ref 1) and its X-ray diffraction pattern was photographed. It was kept at liquid-nitrogen temperature during the X-ray exposure in order to exclude the influence of relaxation. X-ray

X-ray Crystallographic Study of the Temperature Dependence of Metallic Crystal Lattice Distortions

irradiation was carried out by the inverse exposure method in a copper radiation with a sharp-focus X-ray tube having an adjustable focal spot. The (511) lines of aluminium and the (620) lines of lead were studied. The average linear size of the coherent scattering regions and the micro-stresses were found by harmonic analysis of the shape of interference lines. The method of X-ray irradiation and treatment of results has been described more fully by Golik et al (Ref 2). Figs la and 2a the dependence of the average linear size of the coherent scattering regions \overline{D} on the percentage deformation is shown graphically for the investigated metals at the above temperatures. In Figs 1b and 2b the dependence of the average linear size of the coherent scattering regions on deformation temperature is shown. In Fig 3 the same dependence is shown for aluminium. Apart from D, the values of the absolute relative $\sqrt{\frac{L^2}{L}} = \varepsilon$ deformation were also calculated. The nature of change of these factors with drop in

Card 2/4

SOV/126-8-5-9/29

X-ray Crystallographic Study of the Temperature Dependence of Metallic Crystal Lattice Distortions

temperature agrees with the data given by Golik (Ref 2), i.e. a decrease in deformation temperature steadily increases $\sqrt{\Delta L^2}$ and ϵ . The average percentage deformation & was calculated by graphic integration, and averaging along the depth of the column (600 and 800 A for Pb and Al, respectively). A graph representing the dependence of this factor on the degree of deformation for lead specimens deformed at various temperatures is shown in Fig 4. If the value of ϵ is known, the average residual micro-stress can easily be calculated. It is obvious that the modulus of elasticity for a given crystallographic direction and temperature should be included in the calculation. This has proved to be possible for aluminium (Refs 6-8). The results of this calculation are shown in Fig 5, where $\sqrt{\sigma^2}$ is plotted against degree of deformation for various temperatures of deformation. There are 5 figures and 8 references, of which 7 are 4 Soviet and 1 is English.

They were examined in a special low-temperature X-ray camera without being allowed to warm up. Recording was photographic, using (222) reflexions for Ni and Cu, (400) for Al, and (400) and (500) for Pb. The Kal component of the doublet was used, Pines' method of Fourier inversion being applied. Kurdyumov-Lysak's method of using two orders of reflexion was applied for Pb as a control, good agreement being obtained. The curves of the dependence of the dimensions of the coherent scattering regions on time of relaxation showed, particularly in cases of low (5%) increase with T1/2 thereafter. There are 5 figures.

ABSTRACT:

Several months have passed since the competition first started at the above enterprise. A public meeting of Komsomol members was held on June 4. The young people of the enterprise attended

the meeting in order to hear what the situation of the competition was. The following persons took the floor:

Ira Shishova, Secretary of the Komsomol Organization, opened the meeting. The next speaker was Engineer Nelli Rytsk (other members of the brigade are Sinitskaya, Nikolayeva, Spareva, Protasevich), followed by Galya Zozulya, in whose brigade there is also Ludmila Kucheruk (the brigade cooperates closely with the brigade of Mayya Karpyuk), and Tanya Kissa, in whose brigade

are Nadya Polozova, Tamara Tikhonova, Ira Logvinenko,

and peroxidase is decreased under light and increased under dark conditions. The authors explain the increase of photosynthesis intensity in I by the greater photoresistance of the chlorophyll-albumen complex and a higher level of oxidizing-reducing processes. The content of albumen in leaves before the end of August is greater in I, after which time it is greater in II. However, the accumulation of glucose is in reverse ratio: it is greater in II earlier in the year, and greater in I in the autumn. The authors recommend the use of the above indicated physiological-biological indexes for diagnosing the frost-resistant degree of plants in comparing them with local varieties and in selecting prospective hybrides. Abstract

In experiments made in 1951-1954 by the Institute of plant physiology and agrochemistry of the AN UkrSSR the green over the stubble manure under conditions of irrigated agriculture of the southern UkrSSR, improved the physical and physico-chemical soil properties and increased the yield of cotton, torntoes and potatoes. The action of the green manure with the background of P60K45 was greater than the effectiveness of the manure introduced in doses of 20 t/ha. Best results were obtained with white vetch, yellow trigonella
